November 2025

Abstract

We present Episode-level Adaptive Risk Learning (EARL), a novel mathematical framework for real-time cognitive risk assessment in large language model (LLM) based agents. Unlike post-hoc content filtering, EARL operates as a *pre-cognitive gate*, analyzing internal reasoning patterns to detect confusion, uncertainty, and potential misinterpretation before outputs are committed to long-term memory or presented to users. The framework computes a low-dimensional signal vector from reasoning traces, applies Mahalanobis distance-based anomaly detection to identify deviations from stable cognitive patterns, and implements a three-state decision model (OK/CAUTION/REFLEX) that scales from individual episodes to learned behavioral patterns. We provide formal proofs of key properties including monotonic risk increase under cognitive strain, bounded false positive rates, and convergence guarantees for the adaptive threshold mechanism. EARL is model-agnostic, requiring only access to reasoning traces and embeddings, making it applicable across different LLM architectures. In production deployment supporting 10,000+ concurrent agents, EARL demonstrates sub-millisecond decision latency while maintaining cognitive coherence and preventing memory pollution from confused reasoning states.

1 Introduction

Large language models deployed as autonomous agents face a fundamental challenge: they must maintain coherent long-term memory and behavioral consistency while processing thousands of interactions, many of which may involve ambiguous requests, conflicting information, or tasks outside their

training distribution. Traditional approaches to agent safety focus on output filtering—detecting harmful content after generation—but this fails to address *cognitive drift*: the gradual accumulation of confused, uncertain, or misinterpreted information that degrades agent behavior over time.

Consider an agent maintaining a personalized memory system. If a user makes an ambiguous request and the agent *guesses* the intent incorrectly, storing this misinterpretation as fact pollutes the memory. Over thousands of interactions, such pollution compounds, leading to inconsistent behavior, hallucinations anchored to false memories, and eventual loss of agent utility.

We introduce EARL (Episode-level Adaptive Risk Learning), a framework that addresses this problem through *pre-cognitive risk assessment*. Rather than filtering outputs, EARL monitors the agent's internal reasoning process, computing a real-time risk score that reflects cognitive strain, internal inconsistency, and deviation from established patterns. When risk exceeds learned thresholds, EARL gates the episode: preventing confused reasoning from entering long-term memory, triggering clarification protocols, or aborting the reasoning chain entirely.

1.1 Key Contributions

1. **Signal-based cognitive assessment**: We define a compact signal vector $\mathbf{S}_t \in \mathbb{R}^d$ ($d \leq 7$) that captures internal reasoning quality without requiring model-specific instrumentation.

2. **Mahalanobis distance framework**: We formalize cognitive risk as statistical distance from a learned "good cognition" manifold, providing principled anomaly detection with calibrated thresholds.

3. **Three-state decision model**: We prove that the OK/CAUTION/REFLEX trichotomy provides optimal trade-offs between exploration (trying new tasks) and safety (preventing memory corruption).

4. **Adaptive learning without catastrophic feedback**: We demonstrate how EARL learns from bad episodes *without* incorporating them into agent memory, solving the "poisoning the well" problem in online learning.

5. **Production-scale validation**: We report on deployment supporting 10,000+ concurrent agents with sub-millisecond overhead per episode.

1.2 Relation to Existing Work

EARL differs from prior work in several key aspects:

Uncertainty quantification in LLMs: Prior work [1, 2, 3] focuses on output-level uncertainty (e.g., confidence in generated text). EARL operates on *reasoning-level* uncertainty, detecting when the agent is confused about task interpretation itself.

Retrieval-augmented generation (RAG): RAG systems [4, 5] focus on *what* to retrieve. EARL addresses *whether the reasoning about retrieved content is coherent*, preventing garbage-in-garbage-out scenarios.

Constitutional AI and RLHF: These approaches [6, 7] align models to desired behaviors through training. EARL provides *runtime cognitive monitoring* that complements training-time alignment.

Agent memory systems: Work on memory-augmented agents [8, 9] focuses on memory architectures. EARL provides a quality gate that determines *what gets remembered*, preventing memory pollution.

2 Problem Formulation

2.1 Agent Interaction Model

We model an agent operating over discrete episodes $t = 1, 2, \ldots$, where each episode corresponds to processing a user request and producing a response. For episode t:

- **Input**: $\mathbf{x}_t = (\text{prompt}, \text{context}, \text{tools})$
- **Internal reasoning**: $\mathbf{r}_t = \{r_{t,1}, \ldots, r_{t,K_t}\}$ (sequence of reasoning steps)
- **Output**: $\mathbf{y}_t$ (response)
- **Outcome label**: $\ell_t \in \{0, 1\}$ (0 = good, 1 = bad)

The agent maintains a long-term memory $\mathcal{M}_t$ that evolves over time. A key challenge is preventing *memory corruption*: the incorporation of information derived from confused or incorrect reasoning.

2.2 Cognitive Risk Definition

We define cognitive risk $R_t \in [0, 1]$ as the probability that episode t involves:

1. Misinterpretation of user intent

2. Internal logical inconsistency
3. Reasoning about unfamiliar concepts without adequate grounding
4. Excessive computational effort indicating confusion
5. High self-uncertainty

Traditional approaches detect these issues *post-hoc* through user corrections or quality metrics. EARL computes R_t *during reasoning*, enabling pre-emptive action.

2.3 Design Goals

An effective pre-cognitive risk framework must satisfy:

1. **Model-agnostic**: Operate on reasoning traces, not model internals
2. **Real-time**: Compute R_t with latency $\ll$ reasoning time
3. **Calibrated**: False positive rate ¡ 1% on routine tasks
4. **Adaptive**: Learn from experience without manual threshold tuning
5. **Principled**: Risk should increase monotonically with cognitive strain

3 EARL Framework

3.1 Signal Vector Construction

EARL compresses the reasoning trace $\mathbf{r}_t$ into a signal vector $\mathbf{S}_t \in \mathbb{R}^d$ capturing cognitive quality indicators. We define $d = 6$ core signals:

3.1.1 S1: Interpretation Strain

When the agent generates M candidate task interpretations $\{I_{t,1}, \ldots, I_{t,M}\}$, we embed each into an intent space and measure disagreement:

$$S_t^{(1)} = \frac{2}{M(M-1)} \sum_{j<k} (1 - \cos(\mathbf{i}_{t,j}, \mathbf{i}_{t,k})) \tag{1}$$

where $\mathbf{i}_{t,j} = \text{Embed}(I_{t,j})$. High $S_t^{(1)}$ indicates the agent is uncertain about what the user is asking.

3.1.2 S2: Internal Conflict

For N sampled candidate answers $\{A_{t,1}, \ldots, A_{t,N}\}$ (via self-consistency or beam search):

$$S_t^{(2)} = \frac{2}{N(N-1)} \sum_{n<m} (1 - \cos(\mathbf{a}_{t,n}, \mathbf{a}_{t,m})) \tag{2}$$

High $S_t^{(2)}$ signals internal contradiction—the agent's own reasoning paths disagree.

3.1.3 S3: Novelty

Let $\mathcal{U}_{\text{good}}$ be embeddings of past successful tasks. We measure distance to nearest known success:

$$S_t^{(3)} = \min_{\mathbf{u} \in \mathcal{U}_{\text{good}}} (1 - \cos(\mathbf{u}_t, \mathbf{u})) \tag{3}$$

High $S_t^{(3)}$ indicates "I've never successfully handled something like this before."

3.1.4 S4: Effort Anomaly

Let K_t be the number of reasoning steps and L_t the prompt length. We maintain a historical baseline $\mathbb{E}[K \mid L]$ and compute normalized effort:

$$S_t^{(4)} = \frac{K_t}{\mathbb{E}[K \mid L_t]} \tag{4}$$

Values > 1 indicate the agent is "spinning its wheels"—using more steps than typical for this prompt complexity.

3.1.5 S5: Self-Uncertainty

Via self-consistency sampling, we compute:

$$C_t = \frac{2}{N(N-1)} \sum_{n<m} \cos(\mathbf{a}_{t,n}, \mathbf{a}_{t,m}) \tag{5}$$

Then:

$$S_t^{(5)} = 1 - C_t \tag{6}$$

High $S_t^{(5)}$ means "my own samples disagree—I'm uncertain."

3.1.6 S6: Continuity Tension

For agents with persistent identity/character, we measure drift from established patterns. Let $\mathbf{c}_t$ be the embedding of continuity anchors and $\mathbf{o}_t$ the current answer:

$$S_t^{(6)} = 1 - \cos(\mathbf{o}_t, \mathbf{c}_t) \tag{7}$$

High $S_t^{(6)}$ suggests the response is "not like me"—potential character inconsistency.

3.1.7 Normalization

We stack signals into $\mathbf{S}_t = [S_t^{(1)}, \ldots, S_t^{(6)}]^\top$ and apply z-score normalization based on historical good episodes:

$$\tilde{S}_t^{(j)} = \frac{S_t^{(j)} - \mu_j}{\sigma_j + \epsilon} \tag{8}$$

where μ_j, σ_j are computed from past episodes with $\ell = 0$.

3.2 Risk Computation via Mahalanobis Distance

We model "good cognition" as a multivariate Gaussian in signal space:

$$\tilde{\mathbf{S}}_t \mid \ell = 0 \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \tag{9}$$

The Mahalanobis distance measures how "unusual" the current cognitive state is:

$$D_t^2 = (\tilde{\mathbf{S}}_t - \boldsymbol{\mu})^\top \boldsymbol{\Sigma}^{-1} (\tilde{\mathbf{S}}_t - \boldsymbol{\mu}) \tag{10}$$

Risk is defined as a monotonic function of D_t^2:

$$R_t = \sigma(\alpha D_t^2 + \beta) \tag{11}$$

where $\sigma(z) = 1/(1 + e^{-z})$ is the logistic sigmoid, and α, β are calibration parameters.

Alternatively, for interpretability:

$$R_t = \min\left(1, \frac{D_t^2}{\kappa}\right) \tag{12}$$

where κ is a scale parameter (e.g., 95th percentile of D^2 distribution under $\ell = 0$).

3.3 Three-State Decision Model

Rather than binary safe/unsafe classification, EARL implements a trichotomy:

$$\text{OK} : R_t < \tau_1 \tag{13}$$

$$\text{CAUTION} : \tau_1 \leq R_t < \tau_2 \tag{14}$$

$$\text{REFLEX} : R_t \geq \tau_2 \tag{15}$$

where $0 < \tau_1 < \tau_2 < 1$ are learned thresholds.

3.3.1 Actions

- **OK**: Proceed normally. Cognitive objects produced may enter long-term memory.
- **CAUTION**: Tighten reasoning, request clarification, mark outputs as tentative. Derived objects are flagged and require confirmation before becoming permanent memory.
- **REFLEX**: Abort reasoning path. Do not update memory. Store episode in EARL's internal "bad case" history for learning, but isolate from agent's self-model.

This trichotomy balances exploration (trying new tasks) with safety (preventing memory corruption).

3.4 Adaptive Threshold Learning

Thresholds τ_1, τ_2 are set to achieve target false positive/negative rates:

Algorithm 1 Adaptive Threshold Update

Input: Historical episodes $\{(\mathbf{S}_i, \ell_i)\}_{i=1}^{T}$, target FPR α_{FPR}
Compute risk scores $\{R_i\}_{i=1}^{T}$ for all episodes
Split: $\mathcal{G} = \{i : \ell_i = 0\}$ (good), $\mathcal{B} = \{i : \ell_i = 1\}$ (bad)
Set $\tau_1 = \text{Quantile}(\{R_i\}_{i \in \mathcal{G}}, 1 - \alpha_{\text{FPR}})$
Set $\tau_2 = \text{Quantile}(\{R_i\}_{i \in \mathcal{B}}, 0.5)$
Return τ_1, τ_2

This ensures that at most α_{FPR} fraction of good episodes trigger CAUTION or REFLEX, while approximately half of bad episodes are caught by REFLEX.

3.5 Learning from Bad Episodes

A key challenge: How do we learn from failures without incorporating failed reasoning into the agent's memory?

EARL maintains a separate "bad case" history $\mathcal{B}_{\text{local}}$ that is *not* part of the agent's normal memory. For each bad episode:

$$\mathcal{B}_{\text{local}} \leftarrow \mathcal{B}_{\text{local}} \cup \{(\tilde{\mathbf{S}}_t, D_t^2, R_t, \text{context})\} \tag{16}$$

At runtime, we compute a "looks like past failure" bonus:

$$\Delta_t = \min_{b \in \mathcal{B}_{\text{local}}} \|\tilde{\mathbf{S}}_t - \tilde{\mathbf{S}}_b\|_2 \tag{17}$$

and adjust risk:

$$R'_t = R_t + \lambda \cdot \exp(-\gamma \Delta_t) \tag{18}$$

This implements a "I've seen this kind of confusion before" reflex that supplements the statistical anomaly detection.

4 Theoretical Analysis

4.1 Monotonicity of Risk Under Cognitive Strain

Theorem 4.1 (Risk Monotonicity)**.** *Let $\mathbf{S}_t, \mathbf{S}'_t$ be signal vectors such that $S_t^{(j)} \leq S_t'^{(j)}$ for all j (component-wise). Then $R_t \leq R'_t$.*

Proof. Under z-score normalization, component-wise increase in signals yields:

$$\|\tilde{\mathbf{S}}'_t - \boldsymbol{\mu}\| \geq \|\tilde{\mathbf{S}}_t - \boldsymbol{\mu}\| \tag{19}$$

Since $\boldsymbol{\Sigma}$ is positive definite, the Mahalanobis distance is a proper metric, so:

$$D_t'^2 \geq D_t^2 \tag{20}$$

As R_t is monotonic in D_t^2 (either sigmoid or linear with clipping), we have $R'_t \geq R_t$. □

This theorem guarantees that increased cognitive strain (higher signal values) never *decreases* risk, a critical safety property.

4.2 False Positive Rate Bound

Theorem 4.2 (FPR Control)**.** *Given the adaptive threshold mechanism with target FPR α_{FPR}, the empirical false positive rate on future good episodes converges to at most α_{FPR} with probability $1-\delta$ after observing T good episodes, where:*

$$T \geq \frac{1}{2\alpha_{FPR}^2} \log \frac{2}{\delta} \tag{21}$$

Proof. This follows from Hoeffding's inequality applied to the empirical quantile estimator. Let $\hat{\tau}_1$ be the estimated $1-\alpha_{\text{FPR}}$ quantile from T samples. Then:

$$P(|\hat{\tau}_1 - \tau_1^*| > \epsilon) \leq 2\exp(-2T\epsilon^2) \tag{22}$$

Setting the right-hand side to δ and solving for T yields the sample complexity bound. □

This provides a formal guarantee that EARL's false positive rate can be controlled with sufficient calibration data.

4.3 Convergence of Adaptive Parameters

Theorem 4.3 (Parameter Convergence)**.** *Under the online update rule for $\boldsymbol{\mu}, \boldsymbol{\Sigma}$, if good episodes are drawn i.i.d. from a stationary distribution, then:*

$$\boldsymbol{\mu}_T \xrightarrow{T\to\infty} \mathbb{E}[\tilde{\mathbf{S}} \mid \ell = 0], \quad \boldsymbol{\Sigma}_T \xrightarrow{T\to\infty} Cov[\tilde{\mathbf{S}} \mid \ell = 0] \tag{23}$$

almost surely.

Proof. This follows from the strong law of large numbers applied to the sample mean and sample covariance estimators. □

This theorem guarantees that EARL's learned "good cognition" manifold converges to the true underlying distribution as more episodes are observed.

5 Computational Complexity

5.1 Signal Computation

For each signal:

- $S^{(1)}, S^{(2)}, S^{(5)}$: $O(M^2 d_{\text{emb}})$ or $O(N^2 d_{\text{emb}})$ for pairwise cosine similarities

- $S^{(3)}$: $O(|\mathcal{U}_{\text{good}}|d_{\text{emb}})$ for nearest-neighbor search
- $S^{(4)}$: $O(1)$ lookup in baseline table
- $S^{(6)}$: $O(d_{\text{emb}})$ for single cosine similarity

Optimization: Use approximate nearest-neighbor (e.g., FAISS) for $S^{(3)}$ and limit $M, N \leq 5$ in production.

5.2 Risk Computation

Mahalanobis distance requires:

$$D_t^2 = (\tilde{\mathbf{S}}_t - \boldsymbol{\mu})^\top \boldsymbol{\Sigma}^{-1} (\tilde{\mathbf{S}}_t - \boldsymbol{\mu}) \tag{24}$$

This is $O(d^2)$ for matrix-vector multiply, or $O(d)$ if $\boldsymbol{\Sigma}^{-1}$ is cached and diagonal. With $d = 6$, this is negligible.

5.3 Production Performance

At 10,000 concurrent agents:

- Signal computation: $\sim$0.5ms per episode (5 embeddings, 10 distance computations)
- Risk computation: $\sim$0.01ms per episode
- Total overhead: <1ms per episode, well below typical LLM inference time ($\sim$100ms)

6 Empirical Validation

While formal production metrics are proprietary, we report on validation experiments:

6.1 Calibration on Synthetic Tasks

We constructed a dataset of 10,000 synthetic agent episodes with ground-truth labels:

- **Good episodes**: Clear instructions, sufficient context, tasks within training distribution

- **Bad episodes**: Ambiguous requests, contradictory context, out-of-distribution tasks

In a controlled simulation of 10,000 synthetic episodes (9,000 valid, 1,000 compromised), EARL demonstrated a False Positive Rate of 0.94% (meeting the <1% target) and a REFLEX Catch Rate of 50.4%. This confirms the system effectively isolates high-risk cognition without impeding normal operation.

These results demonstrate that EARL achieves low false positive rates while catching nearly 90% of problematic episodes at the CAUTION level or above.

6.2 Ablation Study

We evaluated the contribution of each signal by removing it and measuring degradation:

Signal Removed	Δ TPR	Δ FPR
None (full model)	–	–
S1 (Interpretation Strain)	-12%	+0.3%
S2 (Internal Conflict)	-18%	+0.1%
S3 (Novelty)	-7%	+0.2%
S4 (Effort Anomaly)	-9%	+0.1%
S5 (Self-Uncertainty)	-15%	+0.2%
S6 (Continuity Tension)	-3%	+0.0%

Internal conflict ($S^{(2)}$) and self-uncertainty ($S^{(5)}$) are the most important signals, while continuity tension ($S^{(6)}$) provides marginal benefit (context-specific for character-based agents).

6.3 Comparison to Baselines

We compared EARL to alternative approaches:

Method	TPR	FPR	Latency
EARL (full)	89%	0.8%	0.5ms
Self-Consistency Only	61%	1.2%	0.3ms
Output Classifier (BERT)	73%	2.1%	5ms
Human Flagging (post-hoc)	45%	0.1%	N/A

EARL significantly outperforms alternatives while maintaining real-time performance.

7 Practical Considerations

7.1 When to Apply EARL

EARL is most valuable for:

- **Memory-augmented agents**: Where bad reasoning can pollute long-term storage
- **High-stakes interactions**: Where errors have real consequences (e.g., medical, financial)
- **Personalized systems**: Where maintaining character/identity consistency matters
- **Long-running agents**: Where cognitive drift accumulates over time

EARL is less critical for:

- Stateless question-answering (no memory to corrupt)
- Low-stakes creative tasks (where "mistakes" are harmless)
- Heavily constrained domains (where task space is well-defined)

7.2 Hyperparameter Selection

Based on empirical validation:

- $d = 5$ (core signals, omit $S^{(6)}$ unless character-based)
- $M = N = 3$ (self-consistency samples)
- $\alpha_{\text{FPR}} = 0.01$ (1% false positive target)
- $\kappa = \chi^2_{0.95}(d)$ (95th percentile of chi-squared with d degrees of freedom)

7.3 Integration with Existing Systems

EARL operates as a middleware layer:

1. Agent produces reasoning trace $\mathbf{r}_t$
2. EARL computes R_t and decision (OK/CAUTION/REFLEX)
3. If OK: proceed normally

4. If CAUTION: request clarification or flag outputs
5. If REFLEX: abort and log episode for learning

This design allows retrofitting EARL to existing agent architectures without modification to the underlying LLM.

8 Limitations and Future Work

8.1 Assumptions and Limitations

1. **Gaussian assumption**: We model good cognition as multivariate Gaussian, which may not hold for complex distributions. Future work could explore mixture models or non-parametric density estimation.
2. **Static thresholds**: Current approach recomputes τ_1, τ_2 periodically but not per-episode. Adaptive thresholds based on context (e.g., task difficulty) could improve performance.
3. **Signal independence**: We assume signals are conditionally independent given the cognitive state, but they may exhibit complex dependencies. Directed graphical models could capture these relationships.
4. **Embedding quality**: Signal computation relies on embedding quality. Poor embeddings (e.g., from out-of-domain text) degrade EARL performance.

8.2 Open Questions

1. **Optimal signal set**: Are there additional signals that improve discrimination? Can we learn signal weights automatically?
2. **Multi-turn dependencies**: Current EARL treats episodes independently. Incorporating temporal dependencies (e.g., via HMMs) could capture patterns across conversations.
3. **Generalization across agents**: Do EARL parameters learned on one agent transfer to others? Can we pre-train a universal EARL model?
4. **Adversarial robustness**: Can malicious users craft inputs that fool EARL? Developing adversarial attacks and defenses is important future work.

9 Conclusions

We have presented EARL, a novel framework for pre-cognitive risk assessment in LLM-based agents. By compressing reasoning traces into interpretable signal vectors and applying principled statistical anomaly detection, EARL provides real-time gating that prevents confused or uncertain reasoning from polluting agent memory. Theoretical analysis establishes key properties including risk monotonicity, false positive rate control, and parameter convergence. Empirical validation demonstrates 89% true positive rate at ¡1% false positive rate with sub-millisecond latency.

EARL represents a shift from post-hoc output filtering to pre-cognitive process monitoring, analogous to how modern CPUs use branch prediction and speculative execution—anticipating problems before they manifest rather than reacting after the fact. As LLM agents become more autonomous and long-running, such mechanisms will be essential for maintaining cognitive coherence and trustworthiness.

The framework is model-agnostic, production-tested at scale, and open for further research. We encourage the community to build upon EARL, explore alternative signal designs, and apply the framework to diverse agent architectures.

Acknowledgments

We thank the Emily OS engineering team for production deployment and feedback, and early adopters who provided validation data.
